Introduction to linear regression

Batter up

The movie Moneyball focuses on the "quest for the secret of success in baseball". It follows a low-budget team, the Oakland Athletics, who believed that underused statistics, such as a player's ability to get on base, better predict the ability to score runs than typical statistics like home runs, RBIs (runs batted in), and batting average. Obtaining players who excelled in these underused statistics turned out to be much more affordable for the team.

In this lab we'll be looking at data from all 30 Major League Baseball teams and examining the linear relationship between runs scored in a season and a number of other player statistics. Our aim will be to summarize these relationships both graphically and numerically in order to find which variable, if any, helps us best predict a team's runs scored in a season.

The data

Let's load up the data for the 2011 season.

```
load("more/mlb11.RData")
```

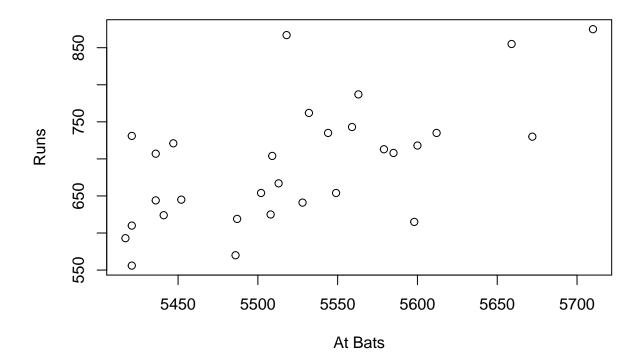

In addition to runs scored, there are seven traditionally used variables in the data set: at-bats, hits, home runs, batting average, strikeouts, stolen bases, and wins. There are also three newer variables: on-base percentage, slugging percentage, and on-base plus slugging. For the first portion of the analysis we'll consider the seven traditional variables. At the end of the lab, you'll work with the newer variables on your own.

1. What type of plot would you use to display the relationship between runs and one of the other numerical variables? Plot this relationship using the variable at_bats as the predictor. Does the relationship look linear? If you knew a team's at_bats, would you be comfortable using a linear model to predict the number of runs?

The type of plot that I would use to display the relationship between runs and at_bats would be a scatterplot. See below for this plot:

```
plot(mlb11$at_bats, mlb11$runs, main="MLB",
    xlab="At Bats", ylab="Runs")
```

MLB

The relationship does appear to look linear. And yes, if I knew a team's at bats I would be comfortable predicting the number of runs.

If the relationship looks linear, we can quantify the strength of the relationship with the correlation coefficient.

```
cor(mlb11$runs, mlb11$at_bats)
```

[1] 0.610627

Sum of squared residuals

Think back to the way that we described the distribution of a single variable. Recall that we discussed characteristics such as center, spread, and shape. It's also useful to be able to describe the relationship of two numerical variables, such as runs and at_bats above.

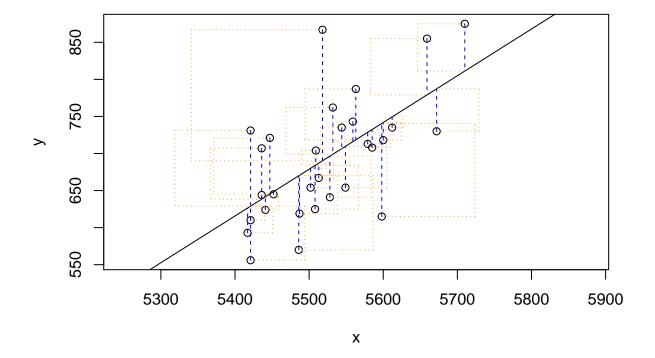

2. Looking at your plot from the previous exercise, describe the relationship between these two variables. Make sure to discuss the form, direction, and strength of the relationship as well as any unusual observations.

From the plot above, it looks like there is a positive linear relationship between runs and at_bats. As the number of at bats increases, the number of runs scored increases. The correlation coefficient of approximately 0.611 also supports this claim since it's positive. There are a few unusual observations, for instance, the New York Yankees had relatively few at-bats (5518), but scored the second most runs out of the 30 teams (867), which doesn't fit well with the majority of teams in the dataset. Additionally, the San Francisco Giants scored the second

fewest runs out of the 30 teams (570), but had more at bats than almost one third of the teams in the dataset.

Just as we used the mean and standard deviation to summarize a single variable, we can summarize the relationship between these two variables by finding the line that best follows their association. Use the following interactive function to select the line that you think does the best job of going through the cloud of points.

```
plot_ss(x = mlb11$at_bats, y = mlb11$runs, showSquares = TRUE)
```

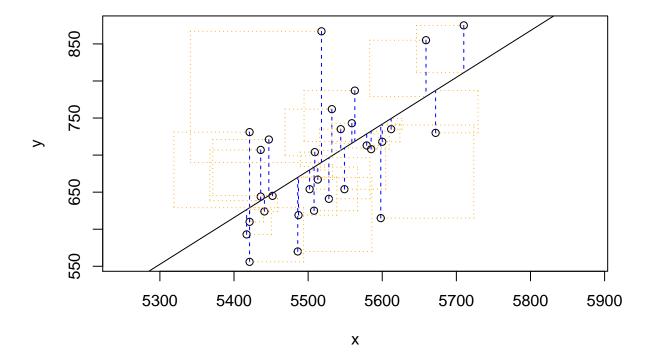

```
## Click two points to make a line.
## Call:
## lm(formula = y ~ x, data = pts)
##
## Coefficients:
## (Intercept) x
## -2789.2429 0.6305
##
## Sum of Squares: 123721.9
```

After running this command, you'll be prompted to click two points on the plot to define a line. Once you've done that, the line you specified will be shown in black and the residuals in blue. Note that there are 30 residuals, one for each of the 30 observations. Recall that the residuals are the difference between the observed values and the values predicted by the line:

$$e_i = y_i - \hat{y}_i$$

The most common way to do linear regression is to select the line that minimizes the sum of squared residuals. To visualize the squared residuals, you can rerun the plot command and add the argument showSquares = TRUE.

```
plot_ss(x = mlb11$at_bats, y = mlb11$runs, showSquares = TRUE)
```

```
## Click two points to make a line.
```

```
## Call:
## lm(formula = y ~ x, data = pts)
##
## Coefficients:
## (Intercept) x
## -2789.2429 0.6305
##
## Sum of Squares: 123721.9
```

Note that the output from the plot_ss function provides you with the slope and intercept of your line as well as the sum of squares.

3. Using plot_ss, choose a line that does a good job of minimizing the sum of squares. Run the function several times. What was the smallest sum of squares that you got? How does it compare to your neighbors?

After running the function several times, the smallest sum of squares value I could come up with was 129877.5. I don't have a neighbor sitting next to me, but I'm assuming that our sum of squares may not be the same, but would be close if we are both attempting to minimize the sum of squared residuals.

```
> plot_ss(x = mlb11$at_bats, y = mlb11$runs, showSquares = TRUE)
Call:
lm(formula = y \sim x, data = pts)
Coefficients:
(Intercept)
                        Х
  -3129.938
                   0.687
Sum of Squares: 149774.1
> plot_ss(x = mlb11$at_bats, y = mlb11$runs, showSquares = TRUE)
Call:
lm(formula = y \sim x, data = pts)
Coefficients:
(Intercept)
                        Х
 -2752.4661
                  0.6195
Sum of Squares:
                 141647.8
```

```
Call:
lm(formula = y \sim x, data = pts)
Coefficients:
(Intercept)
                        Х
 -3007.7780
                   0.6667
Sum of Squares:
                 134844.2
> plot_ss(x = mlb11$at_bats, y = mlb11$runs, showSquares = TRUE)
Call:
lm(formula = y \sim x, data = pts)
Coefficients:
(Intercept)
                        Х
 -2984.0380
                   0.6633
Sum of Squares:
                  129877.5
```

The linear model

It is rather cumbersome to try to get the correct least squares line, i.e. the line that minimizes the sum of squared residuals, through trial and error. Instead we can use the 1m function in R to fit the linear model (a.k.a. regression line).

```
m1 <- lm(runs ~ at_bats, data = mlb11)</pre>
```

The first argument in the function 1m is a formula that takes the form y ~ x. Here it can be read that we want to make a linear model of runs as a function of at_bats. The second argument specifies that R should look in the mlb11 data frame to find the runs and at_bats variables.

The output of 1m is an object that contains all of the information we need about the linear model that was just fit. We can access this information using the summary function.

```
summary(m1)
```

```
##
## Call:
## lm(formula = runs ~ at_bats, data = mlb11)
##
## Residuals:
## Min    1Q Median   3Q Max
## -125.58 -47.05 -16.59   54.40   176.87
##
## Coefficients:
```

```
##
                 Estimate Std. Error t value Pr(>|t|)
## (Intercept) -2789.2429
                            853.6957
                                      -3.267 0.002871 **
## at bats
                   0.6305
                              0.1545
                                       4.080 0.000339 ***
## ---
## Signif. codes:
                   0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 ' ' 1
##
## Residual standard error: 66.47 on 28 degrees of freedom
## Multiple R-squared: 0.3729, Adjusted R-squared: 0.3505
## F-statistic: 16.65 on 1 and 28 DF, p-value: 0.0003388
```

Let's consider this output piece by piece. First, the formula used to describe the model is shown at the top. After the formula you find the five-number summary of the residuals. The "Coefficients" table shown next is key; its first column displays the linear model's y-intercept and the coefficient of at_bats. With this table, we can write down the least squares regression line for the linear model:

```
\hat{y} = -2789.2429 + 0.6305 * atbats
```

One last piece of information we will discuss from the summary output is the Multiple R-squared, or more simply, R^2 . The R^2 value represents the proportion of variability in the response variable that is explained by the explanatory variable. For this model, 37.3% of the variability in runs is explained by at-bats.

4. Fit a new model that uses homeruns to predict runs. Using the estimates from the R output, write the equation of the regression line. What does the slope tell us in the context of the relationship between success of a team and its home runs?

To fit a new model that uses homeruns to predict runs, we'll do the following:

```
m2 <- lm(runs ~ homeruns, data = mlb11)
summary(m2)</pre>
```

```
##
## Call:
## lm(formula = runs ~ homeruns, data = mlb11)
##
## Residuals:
##
      Min
                                3Q
                10
                   Median
                                       Max
   -91.615 -33.410
                     3.231
                            24.292 104.631
##
## Coefficients:
##
              Estimate Std. Error t value Pr(>|t|)
## (Intercept) 415.2389
                           41.6779
                                     9.963 1.04e-10 ***
## homeruns
                 1.8345
                            0.2677
                                     6.854 1.90e-07 ***
##
## Signif. codes: 0 '***' 0.001 '**' 0.05 '.' 0.1 ' ' 1
## Residual standard error: 51.29 on 28 degrees of freedom
## Multiple R-squared: 0.6266, Adjusted R-squared: 0.6132
## F-statistic: 46.98 on 1 and 28 DF, p-value: 1.9e-07
```

We can see from the new model that there is a positive correlation between homeruns and runs. The following equation can be made for this relationship:

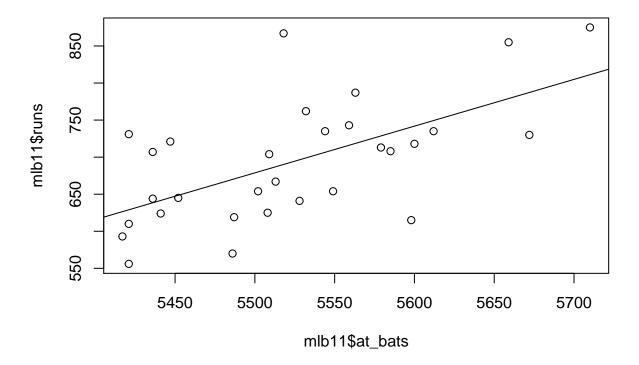

$$\hat{y} = 415.24 + 1.835 * homeruns$$

This signifies that by adding the intercept of 415.24 to 1.835 times the number of homeruns a team hits, we can predict the number of runs this team will score. Since the slope here is a positive 1.835, we can see that the more homeruns a team hits, the more runs the team will score. Therefore, since more runs is connected to the success of a team, we can say that the number of homeruns hit will have a postive relationship with the success of the team.

Prediction and prediction errors

Let's create a scatterplot with the least squares line laid on top.

```
plot(mlb11$runs ~ mlb11$at_bats)
abline(m1)
```

The function abline plots a line based on its slope and intercept. Here, we used a shortcut by providing the model $\mathtt{m1}$, which contains both parameter estimates. This line can be used to predict y at any value of x. When predictions are made for values of x that are beyond the range of the observed data, it is referred to as *extrapolation* and is not usually recommended. However, predictions made within the range of the data are more reliable. They're also used to compute the residuals.

5. If a team manager saw the least squares regression line and not the actual data, how many runs would he or she predict for a team with 5,578 at-bats? Is this an overestimate or an underestimate, and by how much? In other words, what is the residual for this prediction?

We can use this equation to predict the number of runs based on the number of at-bats for a team:

```
\hat{y} = -2789.2429 + 0.6305 * atbats
\hat{y} = -2789.2429 + 0.6305 * (5578)
\hat{y} = 727.6861 runs
```

We can see here that the model would predict 727.69 runs scored based on 5578 at bats. To check to see whether or not this is an overestimate or an underestimate, we can check our dataset:

```
library(tidyverse)
## -- Attaching packages ----- tidyverse 1.
## v ggplot2 3.1.0
                   v purrr
                            0.3.2
## v tibble 2.1.3
                   v dplyr
                            0.8.3
           0.8.2
## v tidyr
                   v stringr 1.4.0
## v readr
           1.1.1
                   v forcats 0.3.0
## Warning: package 'tibble' was built under R version 3.5.2
## Warning: package 'purrr' was built under R version 3.5.2
## Warning: package 'dplyr' was built under R version 3.5.2
## Warning: package 'stringr' was built under R version 3.5.2
## -- Conflicts ------ tidyverse_con
## x dplyr::filter() masks stats::filter()
## x dplyr::lag()
                  masks stats::lag()
library(DescTools)
## Warning: package 'DescTools' was built under R version 3.5.2
x <- mlb11$at bats
mlb11 %>% filter(at_bats == Closest(x, 5578)) %>%
 select(team, runs, at_bats)
                   team runs at_bats
## 1 Philadelphia Phillies 713
                              5579
```

It looks like the closest at_bats count in the dataset is 5579 by the Philadelphia Phillies. With one extra at-bat, they scored 713 runs. Therefore, we would expect 0.6305 runs for one less at-bat, according to our slope, so it would be 712.3695 runs for 5578 at-bats. To calculate the residual of our previous prediction, we have the following calculation:

$$\hat{e} = y_i - \hat{y}$$

$$\hat{e} = 712.3695 - 727.6861$$

$$\hat{e} = -15.3166 runs$$

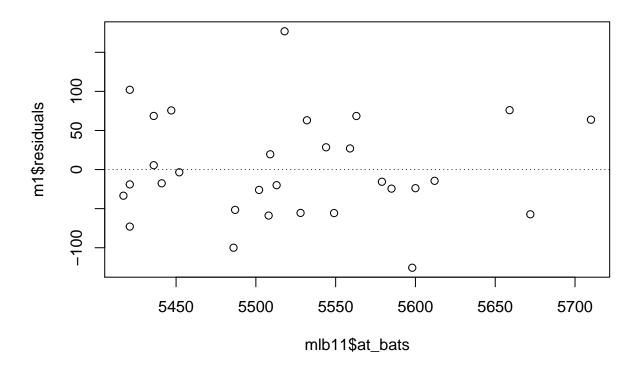

Our model overestimated the number of runs scored by about 15 runs.

Model diagnostics

To assess whether the linear model is reliable, we need to check for (1) linearity, (2) nearly normal residuals, and (3) constant variability.

Linearity: You already checked if the relationship between runs and at-bats is linear using a scatterplot. We should also verify this condition with a plot of the residuals vs. at-bats. Recall that any code following a # is intended to be a comment that helps understand the code but is ignored by R.

```
plot(m1$residuals ~ mlb11$at_bats)
abline(h = 0, lty = 3)  # adds a horizontal dashed line at y = 0
```

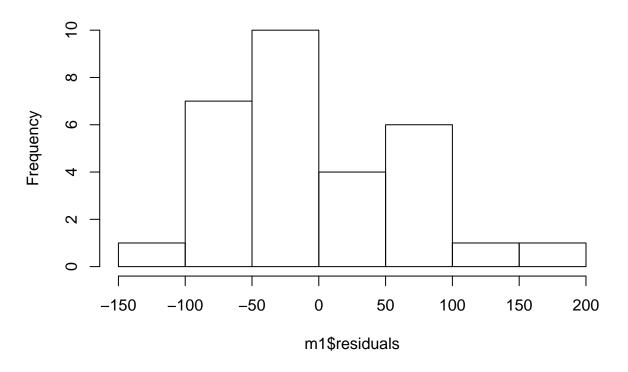

6. Is there any apparent pattern in the residuals plot? What does this indicate about the linearity of the relationship between runs and at-bats?

Nearly normal residuals: To check this condition, we can look at a histogram

hist(m1\$residuals)

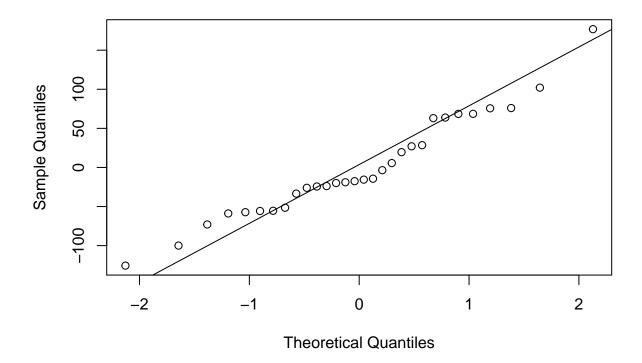

Histogram of m1\$residuals

or a normal probability plot of the residuals.

```
qqnorm(m1$residuals)
qqline(m1$residuals) # adds diagonal line to the normal prob plot
```

Normal Q-Q Plot

7. Based on the histogram and the normal probability plot, does the nearly normal residuals condition appear to be met?

Constant variability:

8. Based on the plot in (1), does the constant variability condition appear to be met?

On Your Own

- Choose another traditional variable from mlb11 that you think might be a good predictor of runs. Produce a scatterplot of the two variables and fit a linear model. At a glance, does there seem to be a linear relationship?
- How does this relationship compare to the relationship between runs and at_bats? Use the R² values from the two model summaries to compare. Does your variable seem to predict runs better than at_bats? How can you tell?
- Now that you can summarize the linear relationship between two variables, investigate the relationships between runs and each of the other five traditional variables. Which variable best predicts runs? Support your conclusion using the graphical and numerical methods we've discussed (for the sake of conciseness, only include output for the best variable, not all five).

- Now examine the three newer variables. These are the statistics used by the author of *Moneyball* to predict a teams success. In general, are they more or less effective at predicting runs that the old variables? Explain using appropriate graphical and numerical evidence. Of all ten variables we've analyzed, which seems to be the best predictor of runs? Using the limited (or not so limited) information you know about these baseball statistics, does your result make sense?
- Check the model diagnostics for the regression model with the variable you decided was the best predictor for runs.
